

# GRAVITATIONAL RECOIL: SIGNATURES ON THE MASSIVE BLACK HOLE POPULATION

MARTA VOLONTERI<sup>1</sup>

*Draft version February 5, 2008*

## ABSTRACT

In the last stages of a black hole merger, the binary can experience a recoil due to asymmetric emission of gravitational radiation. Recent numerical relativity simulations suggest that the recoil velocity can be as high as a few thousands kilometers per second for particular configurations. We consider here the effect of a *worst case scenario* for orbital and phase configurations on the hierarchical evolution of the massive black hole (MBH) population. The orbital configuration and spin orientation in the plane is chosen to be the one yielding the highest possible kick. Masses and spin magnitudes are instead derived self-consistently from the MBH evolutionary models. If seeds form early, e.g. as remnants of the first stars, almost the totality of the first few generation of binaries are ejected. The fraction of *lost* binaries decreases at later times due to a combination of the binary mass ratio distribution becoming shallower, and the deepening of the hosts potential wells. If seeds form at later times, in more massive halos, the retention rate is much higher. We show that the gravitational recoil does not pose a threat to the evolution of the MBH population that we observe locally in either case, although high mass seeds seem to be favored. The gravitational recoil is instead a real hazard for (i) MBHs in biased halos at high-redshift, where mergers are more common, and the potential wells still relatively shallow. Similarly, it is very challenging to retain (ii) MBHs merging in star clusters.

*Subject headings:* cosmology: theory – black holes – galaxies: evolution – quasars: general

## 1. INTRODUCTION

Today, MBHs are ubiquitous in the nuclei of nearby galaxies (see, e.g., Richstone et al. 1998). If MBHs were also common in the past, as implied by the large population of quasars, and if their host galaxies experience multiple mergers during their lifetime, as expected in the currently favored cold dark matter hierarchical cosmologies, then MBH mergers are expected to be relatively common during the cosmic history.

The results of recent numerical relativity simulations question whether MBH mergers represent a threat to the evolution of the MBH population that we observe today. In the final phase of a black hole merger, the inspiral is driven by emission of gravitational radiation. Gravitational waves carry, in general, a non-zero net linear momentum, which establishes a preferential direction for the propagation of the waves. As a consequence, the center of mass of the binary recoils in the opposite direction (Redmount & Rees 1989), possibly causing the ejection of MBHs from the potential wells of their host galaxies (e.g., Madau et al. 2004; Madau & Quataert 2004; Merritt et al. 2004; Volonteri & Rees 2006; Haiman 2004; Schnittman & Buonanno 2007).

The calculations of the magnitude of the recoil have been oscillating in literature by a few orders of magnitude from the early calculations in the Newtonian regime (Fitchett 1983), to the latest analytical approaches (Favata et al. 2004; Blanchet et al. 2005; Damour & Gopakumar 2006). The advent of numerical relativity is now leading to a convergence in the estimates of the recoil. Schwarzschild, i.e., non-spinning, black holes (e.g., Baker et al. 2006) are expected to recoil with velocities below  $200 \text{ km s}^{-1}$ , and a similar range is expected for black holes with low spins, or with spins

(anti-)aligned with the orbital axis (Figure 1). However, when the spin vectors have opposite directions and are in the orbital plane, the recoil velocity can be as large as a few thousands  $\text{km s}^{-1}$  (Campanelli et al. 2007a; González et al. 2007; Campanelli et al. 2007b).

In this paper we assess *if* standard models for MBH evolution (mass and spin) can accommodate a high recoil, and *when* such high recoils are indeed creating hazards during the hierarchical growth of the MBH population. We trace the mass and spin evolution of MBHs from early times, within a plausible scenario for the hierarchical assembly, growth, and dynamics of MBHs in a  $\Lambda$ CDM cosmology, that has been shown to capture many features of the MBH population (e.g., luminosity function of quasars, MBH mass density, core formation due to MBH binary mergers). The main features of the models have been discussed in Volonteri et al. (2003, 2005); Volonteri & Rees (2006); Sesana et al. (2007), and references therein. During a MBH merger, we assume the orbital and phase<sup>2</sup> configuration that leads to the largest recoil magnitude. Black hole masses and spins magnitudes are instead self-consistently determined by the merger and accretion history of the MBHs.

We compare here two different models of MBH formation, one that predicts MBHs to form early, and with low mass, as remnants of the first generation of stars (PopIII stars, cfr. model VHM in Sesana et al. 2007), one which predicts MBHs to form later and with larger masses (cfr. model BVRlf in Sesana et al. 2007), in halos with low angular momentum, prone to large scale instabilities (Begelman et al. 2006). We re-

<sup>2</sup> Campanelli et al. (2007a) also pointed out that the recoil velocity is not uniquely determined solely by the magnitudes and relative directions of the black hole spins in the orbital plane. The recoil was found to vary sinusoidally with the angle between the orbital plane (parallel to the black hole spins) and the initial linear momenta of the holes.

<sup>1</sup> University of Michigan, Astronomy Department, Ann Arbor, MI, 48109

fer the reader to Sesana et al. (2007) for an exhaustive description of the models (including accretion properties and dynamical evolution). We have assessed models with MBH formation more/less efficient than the reference cases. In case of very efficient MBH formation, the mass density on MBHs at  $z \simeq 3$  is much larger than expected from the observed quasar evolution (Yu & Tremaine 2002; Merloni 2004). In models where MBHs form in very small numbers (e.g., BVRhf in Sesana et al. 2007), mergers are very rare events, and happen at later times, with small mass ratios. Clearly, the gravitational rocket is much less of a hazard in models which start from fewer seeds at early times.

FIG. 1.— Recoil velocity of spinning black holes as a function of binary mass ratio,  $q$ . *Solid curves*: spin axis aligned (or anti-aligned) with the orbital angular momentum (Baker et al. 2007). *Dashed curves*: spin axis in the orbital plane (Campanelli et al. 2007). For every mass ratio we plot the combination of spins,  $\hat{a}_1$  and  $\hat{a}_2$  which minimizes (*lower curves*) or maximizes (*upper curves*) the recoil velocity.

## 2. MERGING MBH MASS RATIOS AND SPINS

During a galactic merger, dynamical friction drags in the satellite, along with its central MBH, towards the center of the more massive progenitor. The orbital evolution of the galaxy pair leads also to the destabilization of gas in the merging systems. In simulations, this gas is seen to accumulate towards the centers of the system and fuel the MBHs in both galaxies (e.g., Di Matteo et al. 2005; Kazantzidis et al. 2005; Mayer et al. 2006). When the orbital decay is efficient, the satellite hole moves towards the center of the more massive progenitor, leading to the formation of a bound MBH binary.

The efficiency of dynamical friction decreases with the mass ratio of the merging galaxies, so nearly equal mass galaxy mergers (“major mergers”) lead to efficient binary formation within short timescales (i.e., shorter than the Hubble time), while in “minor mergers” it can take longer than a Hubble time to drag the satellite hole to the center. This effects must be convolved with the mass ratio probability distribution. As the mass function of halos (and galaxies) is steep, the probability of halo mergers decreases with increasing mass ratio, that is, dynamically efficient major mergers are rare, while minor mergers, inefficient in forming MBH binaries, are common.

The combination of those effects leads to a distri-

bution of mass ratios for merging black holes, which is at most redshifts dominated by systems with  $q \equiv M_{MBH2}/M_{MBH1} \leq 1$  in the decade around  $q = 0.1$ . At early times, equal mass MBH mergers are more common, as most mergers involve MBHs which had no time to accrete much mass yet. At later times binaries with small mass ratios are instead much more common, as some MBHs that started their orbital decay during high redshift minor mergers (with an orbital decay timescale comparable to the Hubble time) finally find their way to the central MBH. The lower redshift mass ratio distributions are therefore much shallower (cfr. Sesana et al. 2007): high-speed recoils are common at high redshift, but the typical strength of the recoil decreases with time. Note that the recoil estimates by Baker et al. (2007) and Campanelli et al. (2007a,b) both imply velocities below a few  $\text{km s}^{-1}$  for mass ratios  $q < 0.01$ .

The other two variables determining the recoil velocity (as we have fixed the relative inclination of the spins with respect to each other and the orbital plane) are the MBHs spin magnitudes<sup>3</sup>. MBH spins, in their cosmic evolution, are determined by the sequence of MBH mergers and accretion episodes that build up the MBH mass. In general, mergers of similar mass MBHs increase the spin, while the capture of smaller companions in randomly-oriented orbits tends to spin holes down (Hughes & Blandford 2003). Given our distribution of MBH binary mass ratios, binary coalescences alone do not lead to a dominant spin-up or spin-down of MBHs (cfr. Volonteri et al. 2005). Gas accretion, on the other hand, seems to be more efficient in determining the distribution of MBH spins, due to the alignment between spin and angular momentum of the accretion disc induced by the Lense-Thirring precession.

In our simulations, we assume that in an accretion episode the MBH spin is initially misaligned with respect to the angular momentum of the disc by a random angle, and that the alignment is relatively inefficient, following the scheme described in Volonteri et al. (2005) (eq. 17-19; see Volonteri, Sikora & Lasota 2007 for a more comprehensive model). The spin distributions that we derive are dominated by Kerr MBHs<sup>4</sup>, and are steeper for the spin of the primary (i.e. the most massive hole in the binary), as it typically grows by a larger factor during a given merger.

## 3. DISCUSSION

### 3.1. Signatures on the local MBHs population

Our set of simulations allows to assess the influence of the gravitational recoil under realistic, although rather pessimistic, assumptions. The fraction of merging MBHs that are actually ejected from their hosts, i.e., that have a recoil velocity larger than the escape speed from the host, has a strong dependence on redshift and on the MBH seeds formation mechanism (Figure 2). The escape velocity calculation assumes an NFW halo for the DM

<sup>3</sup> We express the spin through the dimensionless parameter  $\hat{a}$ ,  $S = \hat{a} G m_{BH}^2 / c$ ,  $0 \leq \hat{a} \leq 1$

<sup>4</sup> For simplicity, we will assume in the following that a MBH may be spun up to a maximum equilibrium value of  $\hat{a} = 0.998$  (Thorne 1974), although we note that relativistic magnetohydrodynamic simulations for a series of thick accretion disc models converge at a spin equilibrium of  $\hat{a} \approx 0.93$  (Gammie, Shapiro, & McKinney 2004).

component. The baryonic component is modeled as an isothermal sphere truncated at the radius of the MBH sphere of influence, that is  $r_{inf} = GM_{MBH}/\sigma_g^2$ , where  $M_{MBH}$  is the MBH mass and  $\sigma_g$  is the velocity dispersion.

If seeds form early, in small proto-galaxies, almost the totality of the first few generation of binaries are ejected into the intergalactic medium. The fraction of “lost” binaries decreases at later times due to a combination of (i) the mass ratio distribution becoming shallower, and, (ii) the hierarchical growth of the hosts. The ejected fraction decreases below 50% at  $z \simeq 5$ . If seeds form at later times, in more massive halos, the retention rate is much higher from the beginning, and only about 40-50% of binaries are ejected at all redshifts higher than  $\simeq 3$ .

FIG. 2.— Merger rate of binaries (*solid histogram*) and ejection rate of these binaries (*dashed histogram*), a binary is defined ejected if the recoil velocity is larger than the escape velocity from the host. *Upper panel*: popIII remnants; *lower panel*: direct collapse.

Let us now quantify if these ejection rates indeed disturb the global evolution of the MBH population. The number of MBHs in binaries is a very small fraction of the population at most times (Figure 3) in all the considered cases. In fact, only about 40% of MBHs ever experience a merger, and MBHs evolve in isolation for a large part of their lifetime. As, especially at high redshift, binaries represent the exception, rather than the rule, the possible ejection of most binaries before  $z \simeq 5$  is not a threat to the evolution of the MBH population that has been detected in nearby galaxies. Provided that one or few MBHs per galaxy merger tree (Menou et al. 2001) survive until  $z \simeq 5$ , Soltan-type arguments, which compare the mass density of MBHs in today quiescent galaxies with the mass density inferred from luminous quasars, imply that accretion alone can grow the MBH up to the supermassive variety (Yu & Tremaine 2003).

Figure 4 compares the simulated MBHs that are left in galaxies at  $z = 0$  to the current observational sample (samples from Ferrarese & Ford 2005; and Tremaine et al. 2002, augmented for Lauer et al. 2006 additions; see Valluri et al. 2004 for uncertainties in the MBH mass measurements). The simulated sample broadly follows

the same scaling with galaxy velocity dispersion,  $\sigma_g$ , of the observational sample. By visual inspection, the simulated MBHs display some “outliers” with masses below the predictions of the MBH mass -  $\sigma_g$  scaling. Given the small observational sample, and the uncertainties on the MBH masses, we ran a Montecarlo test to compare the observational datasets to our simulations (cfr. Wyithe 2006); we conclude that statistically we cannot rule out that the simulated sample is compatible with observations (at the  $2\text{-}\sigma$  level), at least for MBHs hosted in galaxies with velocity dispersion larger than  $\gtrsim 100 \text{ km s}^{-1}$ . Additionally, observations are biased against the detection of “under-massive black holes”, with respect to the expectations of the MBH mass -  $\sigma_g$  scaling, given the scaling of the radius of the sphere of influence.

FIG. 3.— Number density of MBHs (*upper curves*) and binaries (*lower curves*). The fraction of MBHs in binaries is very small at most times. *Upper panel*: direct collapse. *Lower panel*: popIII remnants.

Models with large MBH seed masses appear to be favored in a high recoil velocity scenario. However, note that the  $1\text{-}\sigma$  dispersions of the two samples, (Ferrarese & Ford 2005; Tremaine et al. 2002) are compatible, but not identical. The fraction of outliers can differ up to a factor of two between the two samples for galaxies with velocity dispersion below  $200 \text{ km s}^{-1}$ . The uncertainties and small size of the observational sample contribute to prevent to draw firm conclusions: a larger sample of measured MBH masses, which can be available to future instruments, such as Giant Magellan Telescope, can help assess the relative importance of the gravitational rocket.

We recall here that we have adopted the orbital configuration yielding the highest recoil velocities, which, as pointed out by Bogdanovic et al. (2007) is probably rather uncommon. Also, Campanelli et al. (2007a) discuss how the sinusoidal dependence on the orbital phase implies a reduction of  $\sqrt{2}$  in the root-mean-square recoil velocity, in case of optimal orbital configuration with random phase configuration. The fraction of outliers that we find represents therefore an upper limit, and our results

emphasize also the necessity of further investigations on the orbital and phase configuration expected in merging MBH binaries.

FIG. 4.— The  $M_{\text{SMBH}}$ –velocity dispersion ( $\sigma_c$ ) relation at  $z = 0$ . Every circle represents the central MBH in a halo of given  $\sigma_c$ . Observational data are marked by their quoted errorbars, both in  $\sigma_c$ , and in  $M_{\text{SMBH}}$  (Tremaine et al. 2002). *Left*: popIII remnants; *right*: direct collapse. *Upper panels*: fraction of galaxies at a given velocity dispersion which do not have a central SMBH.

### 3.2. Special cases

While Figure 2 is reassuring with respect to the “average” MBH, as the simulations sample a statistical ensemble of galaxy halos, it is not representative of very rare, highly biased regions, where MBH formation is more common, and so are binary MBHs. Haiman (2004) pointed out that the recoil can be indeed threatening the growth of the MBHs that are believed to be powering the luminous quasars at  $z \simeq 6$  detected in the Sloan survey (e.g., Fan et al. 2001). In fact, in such a biased volume, the density of halos where MBH formation can be efficient (either by direct collapse, or via PopIII stars) is highly enhanced. The net result is an higher fraction of binary systems, and binarity is especially common for

the central galaxy of the main halo. While the “average” MBH experiences at most one merger in its lifetime, a MBH hosted in a rare exceptionally massive halo can experience up to a few tens mergers, and the probability of ejecting the central MBH, halting its growth, is 50-80% at  $z > 6$ . Volonteri & Rees (2006) demonstrated that this result is not dependent on the “optimal” orbital and phase configuration. This implies that MBHs at high redshift did not mainly grow via mergers, as proposed in works that did not take the gravitational recoil into consideration (e.g., Pelupessy et al. 2007; Li et al. 2006).

Another special case, at the other very end of the MBH mass scale, is represented by merging MBHs in star clusters. It has been proposed (e.g., Portegies Zwart et al. 2004; Gürkan et al. 2004) that the merging of main-sequence stars via direct physical collisions can enter into a runaway phase, and form a very massive star, which may then collapse to form a MBH. A more exotic outcome of the process can happen in star clusters with a relatively large (but well within the expected values) primordial binary fraction: the formation of two MBHs (Gürkan et al. 2006). Star collisions likely transfer angular momentum to the very massive star, and a rotating very massive star plausibly collapses into a spinning MBH (Saijo et al. 2002). If the two star cluster MBHs form with a mass ratio larger than  $q = 0.1$ , when they proceed to coalescence (Gültekin et al. 2004, 2006; Fregeau et al. 2006), the magnitude of the recoil for most configurations is larger than 50  $\text{km s}^{-1}$ , leading to a high escape probability. If formation of binary MBHs is common in star clusters, their ejection is highly likely as well. A similar fate would await MBHs binaries forming following the merger of two star cluster, each with a MBH (Amaro-Seoane & Freitag 2006). Although in both cases the MBH binary would be a source of gravitational radiation, which might allow to confirm the predictions of the previous scenario for MBH formation in cluster, after the ejection the MBHs would join the very difficult to detect population of wandering MBHs (Volonteri & Perna 2005; Mapelli et al. 2006; Kuranov et al. 2007). (Volonteri et al. 2007)

We wish to acknowledge enlightening discussions with D. Richstone and K. Gültekin.
